CS 188: Artificial Intelligence

Markov Decision Processes II

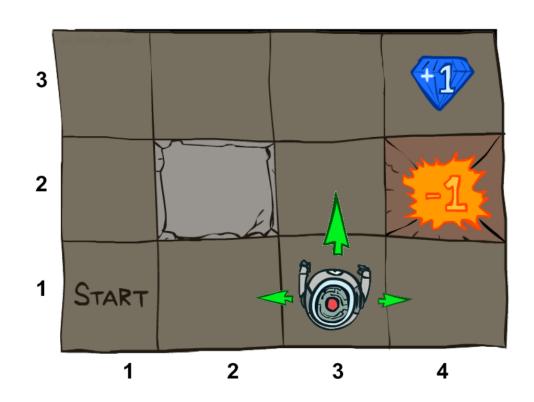

Instructors: Davis Foote and Jacob Andreas --- University of California, Berkeley

[Slides by Dan Klein, Pieter Abbeel, Anca Dragan, Davis Foote, Jacob Andreas; http://ai.berkeley.edu.]

Example: Grid World

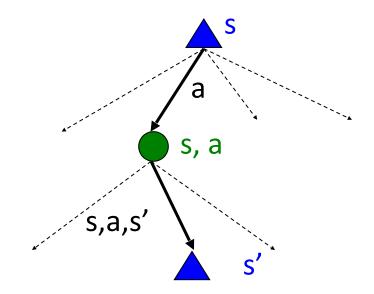

- A maze-like problem
 - The agent lives in a grid
 - Walls block the agent's path
- Noisy movement: actions do not always go as planned
 - 80% of the time, the action North takes the agent North
 - 10% of the time, North takes the agent West; 10% East
 - If there is a wall in the direction the agent would have been taken, the agent stays put
- The agent receives rewards each time step
 - Small "living" reward each step (can be negative)
 - Big rewards come at the end (good or bad)
- Goal: maximize sum of (discounted) rewards

Recap: MDPs

Markov decision processes:

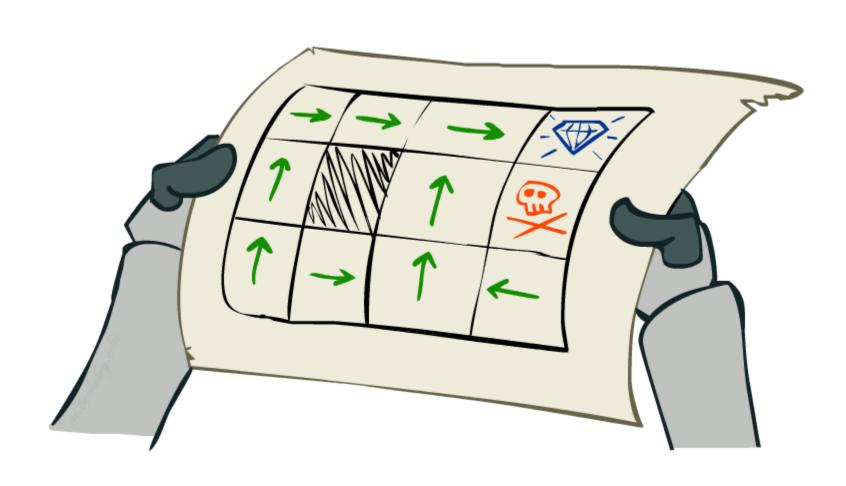

- States S
- Actions A
- Transitions P(s'|s,a) (or T(s,a,s'))
- Rewards R(s,a,s') (and discount γ)
- Start state s₀

• Quantities:

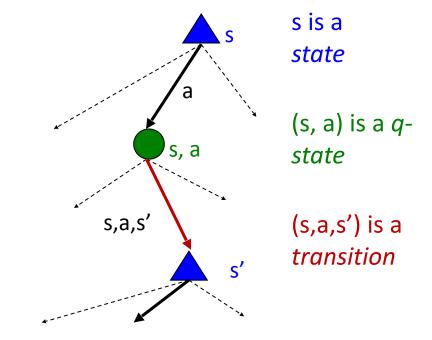

- Policy = map of states to actions
- Utility = sum of discounted rewards
- Values = expected future utility from a state (max node)
- Q-Values = expected future utility from a q-state (chance node)

Solving MDPs

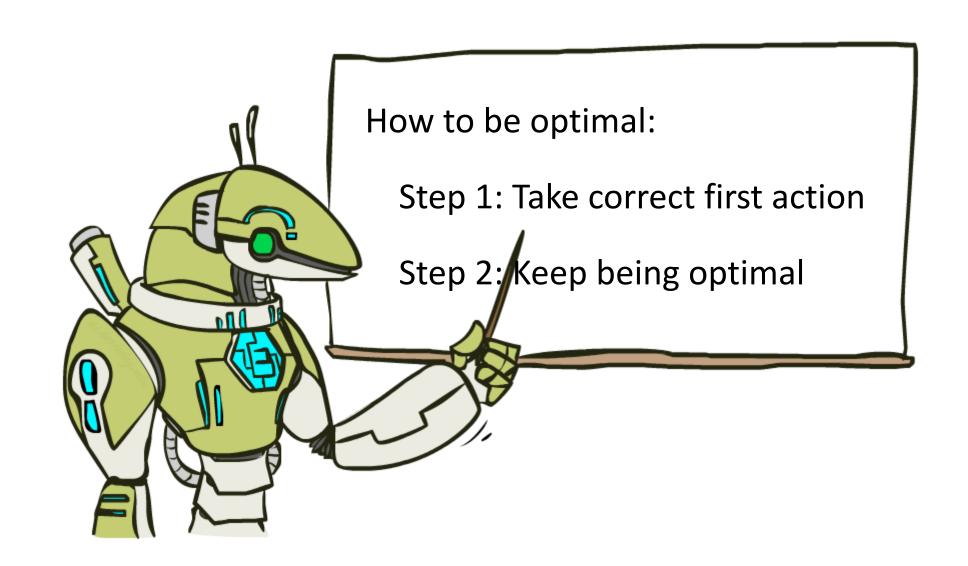

Optimal Quantities

- The value (utility) of a state s:
 - V*(s) = expected utility starting in s and acting optimally
- The value (utility) of a q-state (s,a):
 - Q*(s,a) = expected utility starting out having taken action a from state s and (thereafter) acting optimally

- The optimal policy:
 - $\pi^*(s)$ = optimal action from state s

The Bellman Equations

The Bellman Equations

 Definition of "optimal utility" via expectimax recurrence gives a simple one-step lookahead relationship amongst optimal utility values

$$V^{*}(s) = \max_{a} Q^{*}(s, a)$$

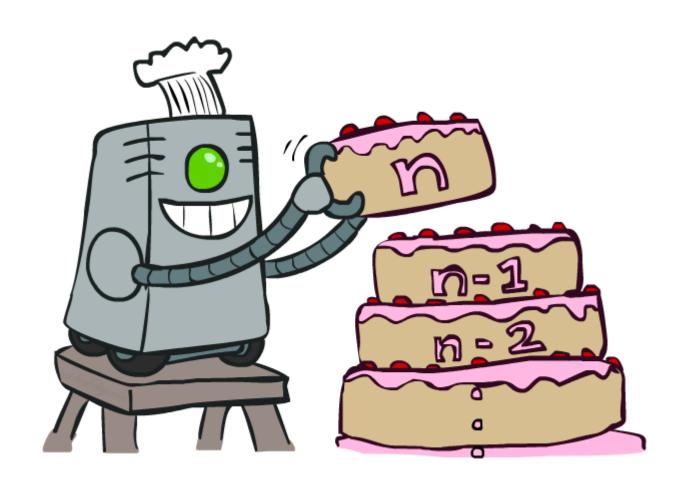

$$Q^{*}(s, a) = \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V^{*}(s') \right]$$

$$V^{*}(s) = \max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V^{*}(s') \right]$$

 These are the Bellman equations, and they characterize optimal values in a way we'll use over and over

Value Iteration

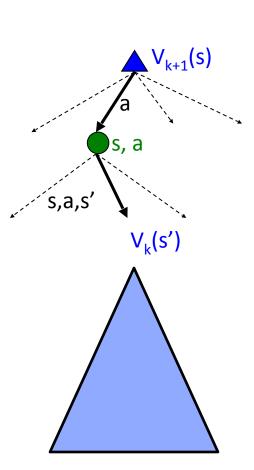

Value Iteration

- Start with $V_0(s) = 0$: no time steps left means an expected reward sum of zero
- Given vector of $V_k(s)$ values, do one ply of expectimax from each state:

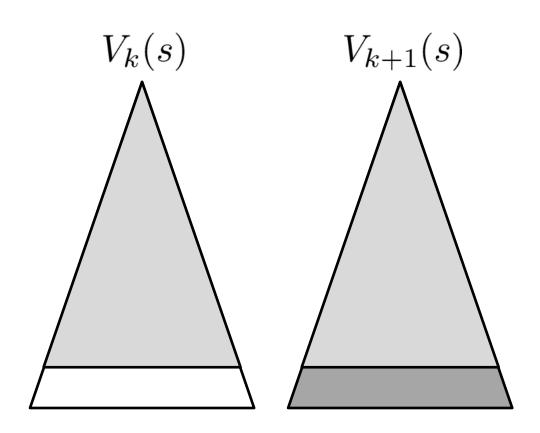

$$V_{k+1}(s) \leftarrow \max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V_k(s') \right]$$

- Repeat until convergence
- Complexity of each iteration: O(S²A)
- Theorem: will converge to unique optimal values
 - Basic idea: approximations get refined towards optimal values
 - Policy may converge long before values do

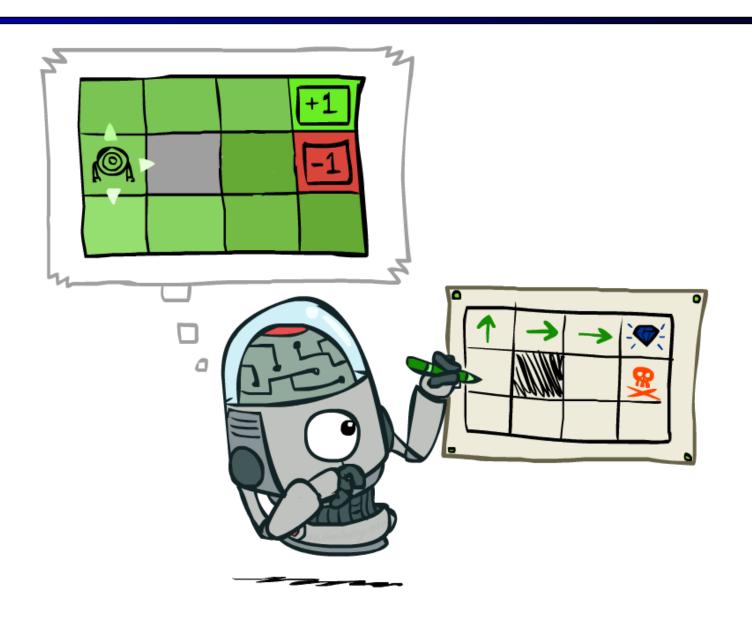

Convergence*

- How do we know the V_k vectors are going to converge?
- Case 1: If the tree has maximum depth M, then V_M holds the actual untruncated values
- Case 2: If the discount is less than 1
 - Sketch: For any state V_k and V_{k+1} can be viewed as depth k+1 expectimax results in nearly identical search trees
 - The difference is that on the bottom layer, V_{k+1} has actual rewards while V_k has zeros
 - That last layer is at best all R_{MAX}
 - It is at worst R_{MIN}
 - But everything is discounted by γ^k that far out
 - So V_k and V_{k+1} are at most γ^k max | R | different
 - So as k increases, the values converge

Policy Extraction

Computing Actions from Values

- Let's imagine we have the optimal values V*(s)
- How should we act?
 - It's not obvious!
- We need to do a mini-expectimax (one step)

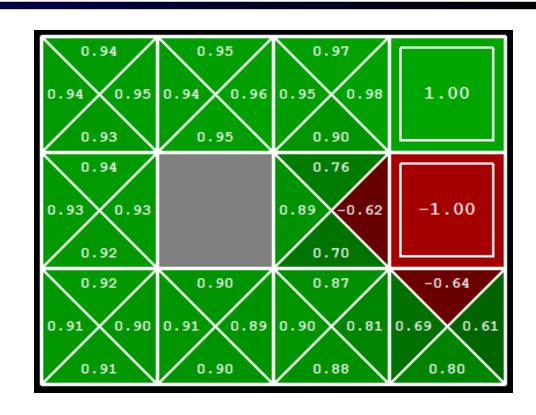

$$\pi^*(s) = \arg\max_{a} \sum_{s'} T(s, a, s') [R(s, a, s') + \gamma V^*(s')]$$

This is called policy extraction, since it gets the policy implied by the values

Computing Actions from Q-Values

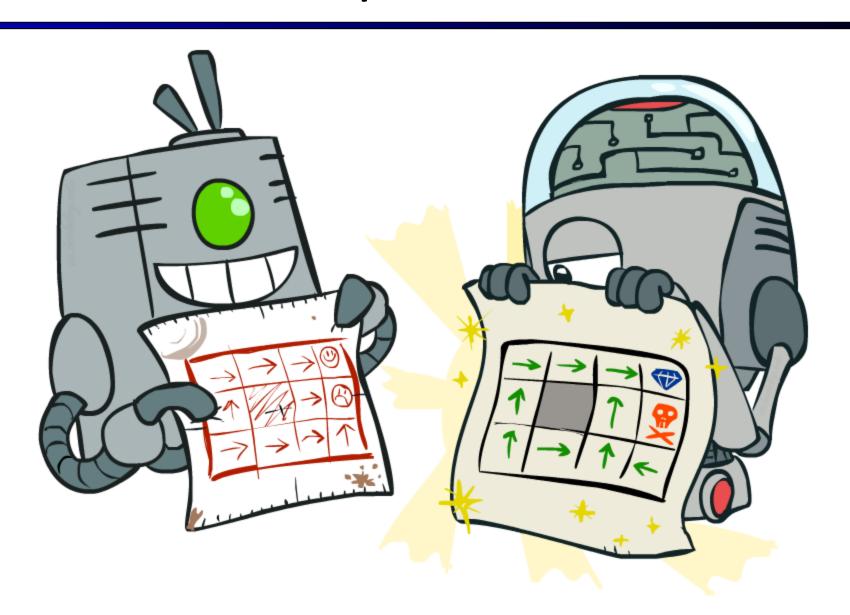

- Let's imagine we have the optimal q-values:
- How should we act?
 - Completely trivial to decide!

$$\pi^*(s) = \arg\max_{a} Q^*(s, a)$$

Important lesson: actions are easier to select from q-values than values!

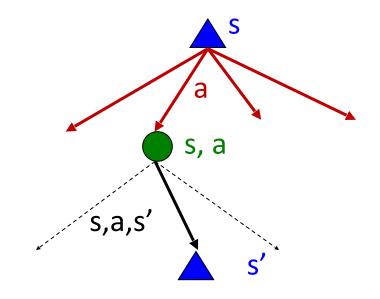

Policy Methods

Problems with Value Iteration

Value iteration repeats the Bellman updates:

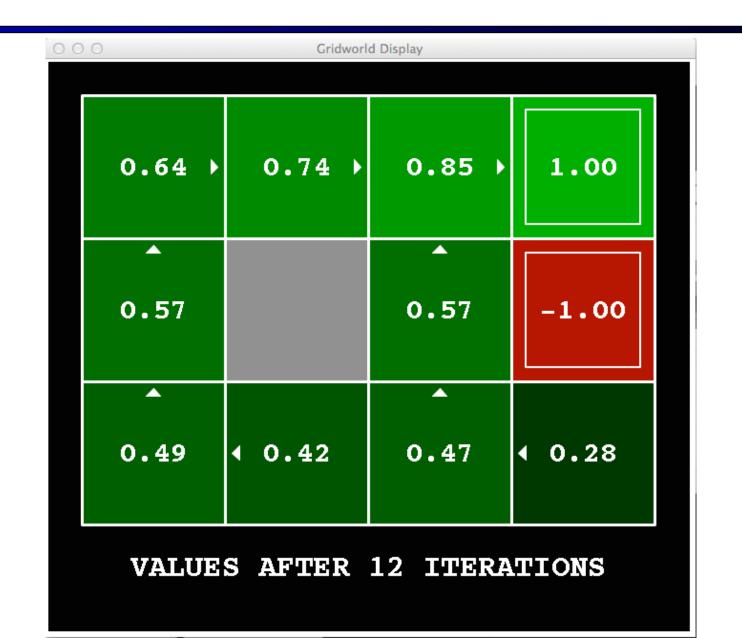

$$V_{k+1}(s) \leftarrow \max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V_k(s') \right]$$

■ Problem 1: It's slow – O(S²A) per iteration

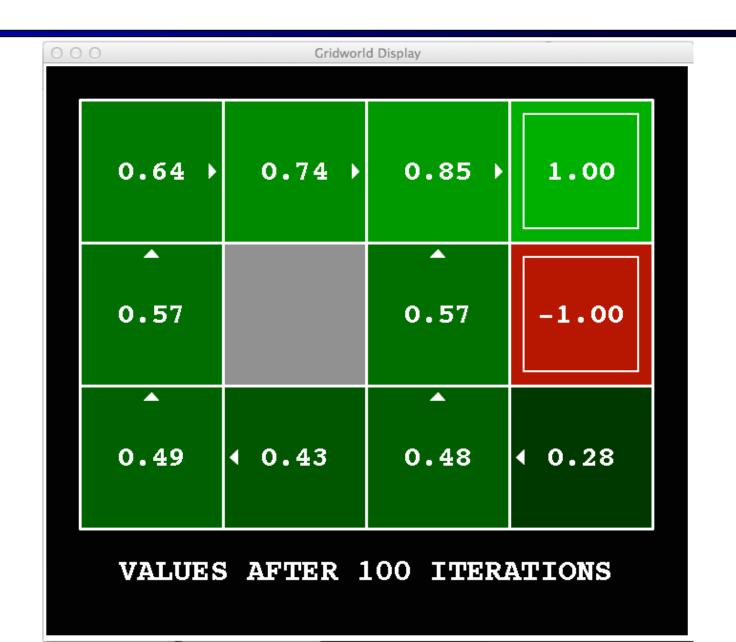

- Problem 2: The "max" at each state rarely changes
- Problem 3: The policy often converges long before the values

k=12

Noise = 0.2 Discount = 0.9 Living reward = 0

k=100

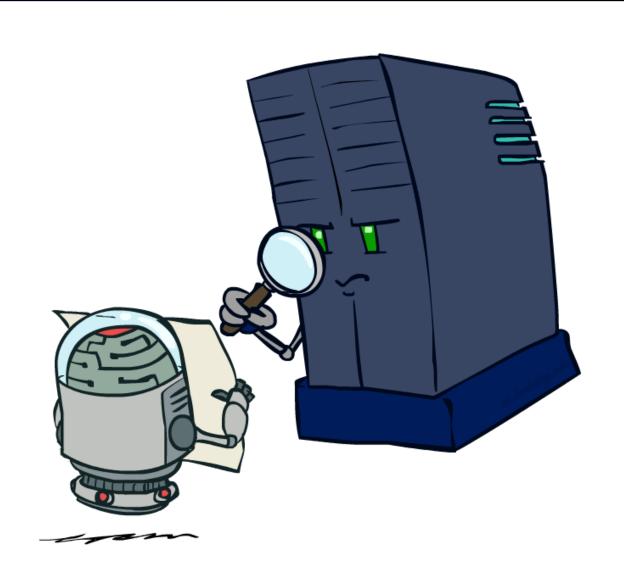

Noise = 0.2 Discount = 0.9 Living reward = 0

Policy Iteration

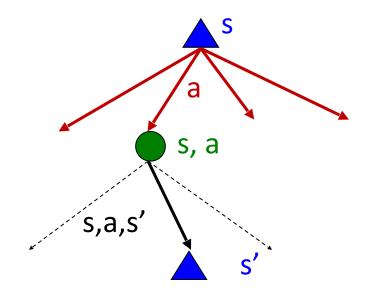

- Alternative approach for optimal values:
 - Step 1: Policy evaluation: calculate utilities for some fixed policy (not optimal utilities!) until convergence
 - Step 2: Policy improvement: update policy using one-step look-ahead with resulting converged (but not optimal!) utilities as future values
 - Repeat steps until policy converges
- This is policy iteration
 - It's still optimal!
 - Can converge (much) faster under some conditions

Policy Evaluation

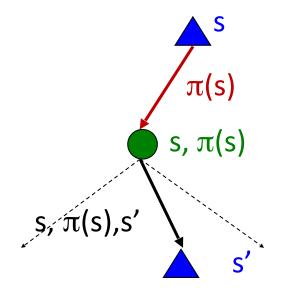

Fixed Policies

Do the optimal action

Do what π says to do

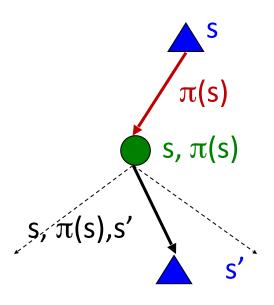

- Expectimax trees max over all actions to compute the optimal values
- If we fixed some policy $\pi(s)$, then the tree would be simpler only one action per state
 - ... though the tree's value would depend on which policy we fixed

Utilities for a Fixed Policy

- Another basic operation: compute the utility of a state s under a fixed (generally non-optimal) policy
- Define the utility of a state s, under a fixed policy π : $V^{\pi}(s)$ = expected total discounted rewards starting in s and following π
- Recursive relation (one-step look-ahead / Bellman equation):

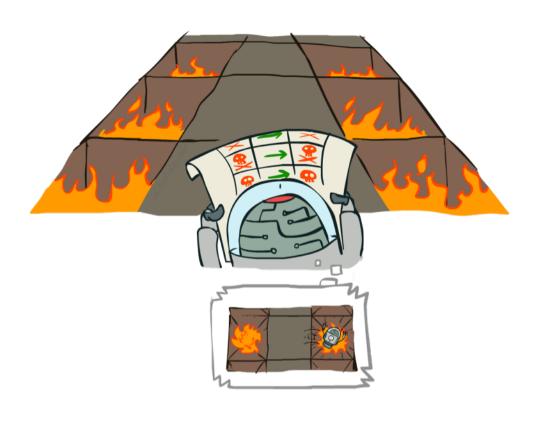

$$V^{\pi}(s) = \sum_{s'} T(s, \pi(s), s') [R(s, \pi(s), s') + \gamma V^{\pi}(s')]$$

Example: Policy Evaluation

Always Go Right

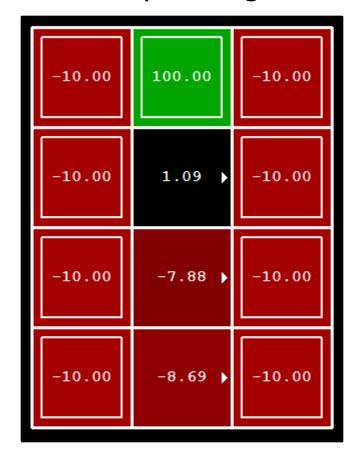

Always Go Forward

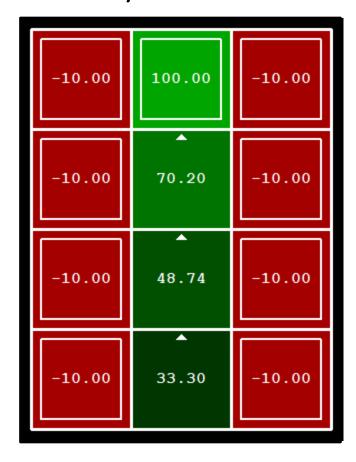

Example: Policy Evaluation

Always Go Right

Always Go Forward

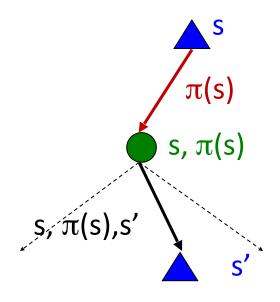

Policy Evaluation

- How do we calculate the V's for a fixed policy π ?
- Idea 1: Turn recursive Bellman equations into updates (like value iteration)

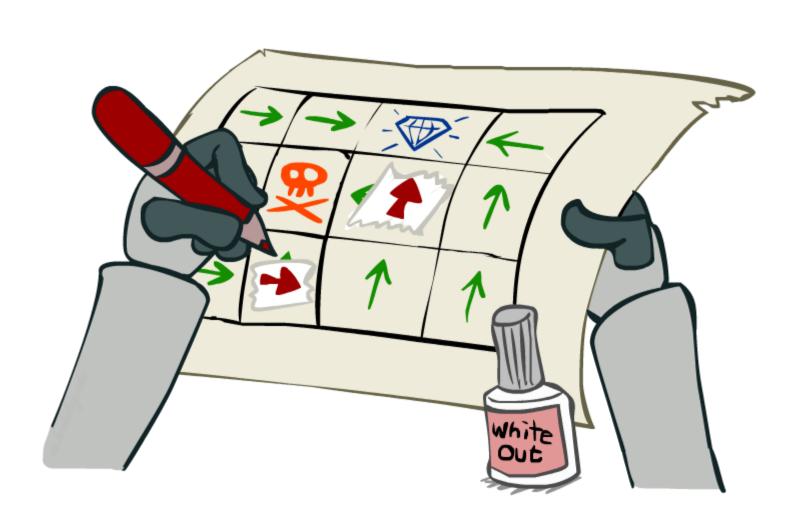

$$V_0^{\pi}(s) = 0$$

$$V_{k+1}^{\pi}(s) \leftarrow \sum_{s'} T(s, \pi(s), s') [R(s, \pi(s), s') + \gamma V_k^{\pi}(s')]$$

- Efficiency: O(S²) per iteration
- Idea 2: Without the maxes, the Bellman equations are just a linear system
 - Solve with Matlab (or your favorite linear system solver)

Policy Iteration

Policy Iteration

- Evaluation: For fixed current policy π , find values with policy evaluation:
 - Iterate until values converge:

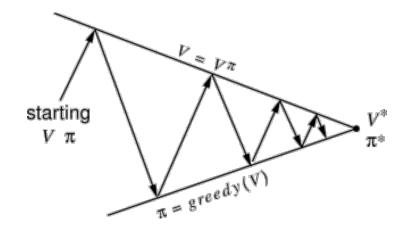

$$V_{k+1}^{\pi_i}(s) \leftarrow \sum_{s'} T(s, \pi_i(s), s') \left[R(s, \pi_i(s), s') + \gamma V_k^{\pi_i}(s') \right]$$

- Improvement: For fixed values, get a better policy using policy extraction
 - One-step look-ahead:

$$\pi_{i+1}(s) = \arg\max_{a} \sum_{s'} T(s, a, s') \left[R(s, a, s') + \gamma V^{\pi_i}(s') \right]$$

Why Does This Work?

- Policy improvement theorem: If for all $s \in S$, $Q^{\pi}(a, \pi'(s)) \ge V^{\pi}(s)$, then $V^{\pi'}(s) \ge V^{\pi}(s)$.
 - Key idea: if at every state, following π' for one action is better than following π then following π' forever is better than following π forever
- Dueling subroutines:
 - Suppose our policy is the right one. What is the value?
 - Suppose our values are the right ones. What is the optimal policy?
 - Creates two alternating constrained optimization problems that eventually converge to optimality

- At all steps, either we improve or hit a fixed point
- Only fixed point is optimality, since being fixed with respect to Bellman update equations gives optimality

Comparison

Both value iteration and policy iteration compute the same thing (all optimal values)

In value iteration:

- Every iteration updates both the values and (implicitly) the policy
- We don't track the policy, but taking the max over actions implicitly recomputes it

In policy iteration:

- We do several passes that update utilities with fixed policy (each pass is fast because we consider only one action, not all of them)
- After the policy is evaluated, a new policy is chosen (slow like a value iteration pass)
- The new policy will be better (or we're done)
- Both are dynamic programs for solving MDPs

Summary: MDP Algorithms

So you want to....

- Compute optimal values: use value iteration or policy iteration
- Compute values for a particular policy: use policy evaluation
- Turn your values into a policy: use policy extraction (one-step lookahead)

These all look the same!

- They basically are they are all variations of Bellman updates
- They all use one-step lookahead expectimax fragments
- They differ only in whether we plug in a fixed policy or max over actions

Double Bandits

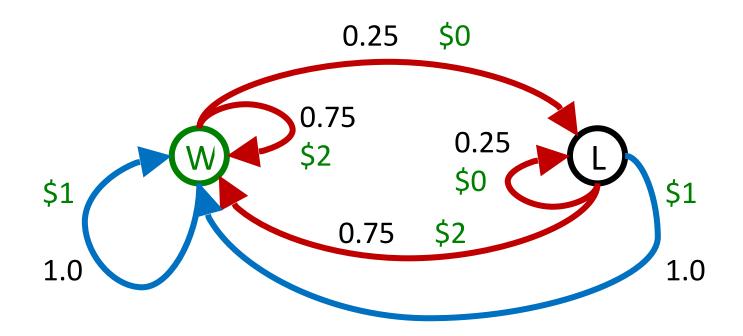

Double-Bandit MDP

Actions: Blue, Red

States: Win, Lose

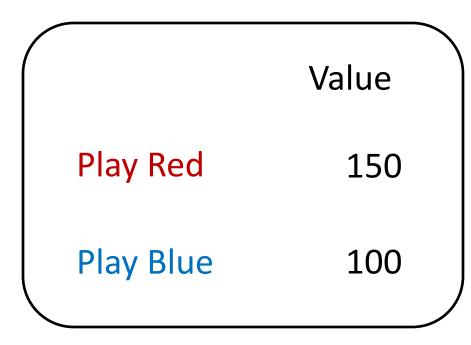

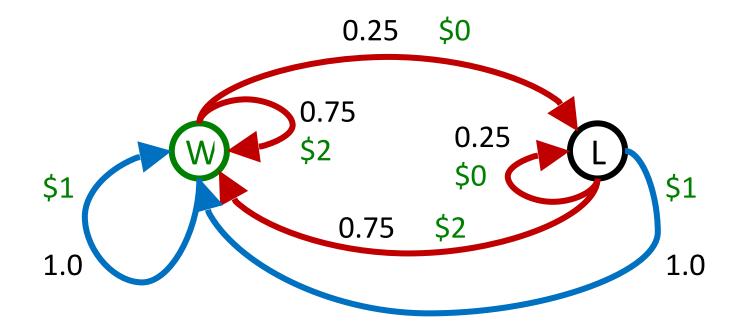

No discount
100 time steps
Both states have
the same value

Offline Planning

- Solving MDPs is offline planning
 - You determine all quantities through computation
 - You need to know the details of the MDP
 - You do not actually play the game!

No discount
100 time steps
Both states have
the same value

Let's Play!

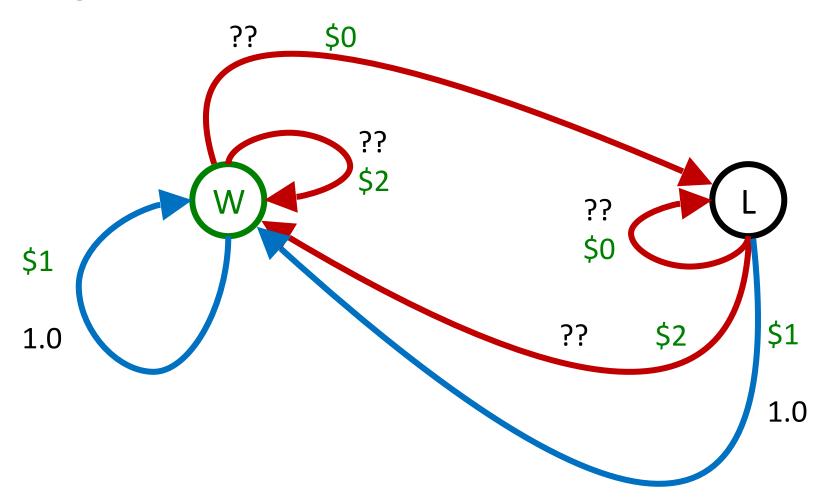

\$2 \$2 \$0 \$2 \$2

\$2 \$2 \$0 \$0 \$0

Online Planning

Rules changed! Red's win chance is different.

Let's Play!

\$0 \$0 \$0 \$2 \$0

\$2 \$0 \$0 \$0 \$0

What Just Happened?

- That wasn't planning, it was learning!
 - Specifically, reinforcement learning
 - There was an MDP, but you couldn't solve it with just computation
 - You needed to actually act to figure it out

- Exploration: you have to try unknown actions to get information
- Exploitation: eventually, you have to use what you know
- Regret: even if you learn intelligently, you make mistakes
- Sampling: because of chance, you have to try things repeatedly
- Difficulty: learning can be much harder than solving a known MDP

Next Time: Reinforcement Learning!
